More on implementing maps

- Arrays and Lists? Too inefficient! Linear runtimes
- Plain BSTs? Too inefficient! Linear runtimes
- RB-trees? Good choice! Logarithmic runtimes are guaranteed

Can we do better in practice?

Answer

HASH TABLES

 \square With hash-tables, it is not possible to obtain a sorted sequence of the records in O(n) time like BSTs.

Warm up (the simplest possible case)

INDEX/KEY	0	1	2	3	4	5	6	7	8	9	10
Value	D		Z			C	Q				

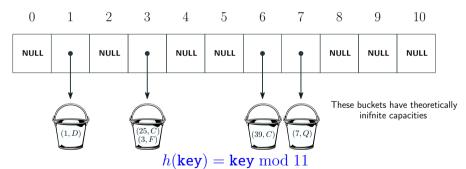

Assume that we have $n \leq 11$ records to maintain where the keys are in the range [0,10] Insertions, deletions, look-ups can be executed in O(1) time each since an array of length N=11 can be used for implementing the table

The situation

- Let n be the number of records stored and N be the number of possible keys
- What if N is really large, say in the order of millions and n much less than N?
- **Example.** for integer keys, $N=2^{31}-1=2,147,483,647$; but, n is most cases is much less than $2^{31}-1$. Are we still going to use an array of size 2,147,483,647? Probably not a good idea. Space wastage may be severe. Storing such an array will require $(2^{31}-1)\times 4$ bytes ≈ 8.7 GB of space!

A space-efficient solution

Map the keys to the set of array indices using some function (a.k.a. hash function). Every index can hold more than one records (a bucket of records). In this case, more than N records can be maintained!

For any key k, $0 \le h(k) \le 10$

The record (k, v) is put in the bucket at index h(k)

What if the keys are not integers?

- 1 Convert the non-integer key to an integer using some function h_1 ; after applying h_1 , we get an integer $h_1(k)$; the function h_1 is known as the **hashcode**
- ② Next, map $h_1(k)$ to an array index using another function h_2 known as the **compression function**

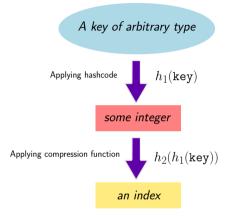

The record (k, v) maps to the index $h_2(h_1(k))$

Example

```
h_1("{\tt Doctor\ Strange"}) = 1938383 h_2(1938383) = 1938383 \bmod N, where p is the size of the array
```

 \blacksquare In the previous example, N=11

The hashcode and the compression function

Hash function

$$h = h_2(h_1(k))$$

The array plus the hash function is called **hash-table**

The main idea behind hashing

It is *unlikely* that two different records (k_i, v_i) and (k_j, v_j) , where $k_i \neq k_j$ will map to the same bucket in the hash table when the size of the table N is sufficiently large and the hash function is chosen appropriately. Consequently, it is unlikely that the buckets will be crowded.

If the buckets are not crowded, searches, insertions, and deletions would run fast in practice.

Hashcodes

- Based on the type of keys we are using, one can design various kinds of hashcodes
- Desired properties of hash codes:
 - If two keys k_i, k_j are different, then the two corresponding outputs of hashcode should be different

$$k_i \neq k_j \implies h_1(k_i) \neq h_1(k_j)$$

- Should be very fast to compute
- In Java, the Object class (super-class of every Java class) defines the hashCode() method using the object's memory address
- This means the hashCode() method can be invoked on any object!
- If two objects are equal according to the optional equals method of the class, then calling the hashCode method on each of the two objects must produce the same integer result.

Illustration

Java's hashcode for Strings

Let $s = s_0 s_1 \dots s_{n-1}$, where every s_i is a character $h_1(s) = (\mathsf{ASCII}(s_0) \times 31^{n-1}) + (\mathsf{ASCII}(s_1) \times 31^{n-2}) + \dots + (\mathsf{ASCII}(s_{n-1}) \times 31^0)$

```
public class HashCodeDemo {
   public static void main(String[] args) {
      String s1 = "UNF is FUN";
      String s2 = "FUN is UNF";
      String s3 = "UNF iss FUN";

      System.out.print(s1.hashCode() + " ");
      System.out.print(s2.hashCode() + " ");
      System.out.print(s3.hashCode());
   }
}
```

Output

120001564 63052472 -499412747

Java

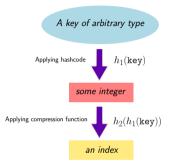

• The built-in Java classes such as String, Integer, Double, etc. redefine this function; see Java's documentation to see the precise mathematical functions

```
Double d1 = 101.98;
System.out.print(d1.hashCode() + " ");
d1 = 101.981;
System.out.print(d1.hashCode() + " ");
d1 = -101.981;
System.out.print(d1.hashCode() + " ");
```

Output

296942503 -195025192 1952458456

Compression function

The division method

$$h_2(x) = x \bmod N$$

where N is the size of the table.

Collisions

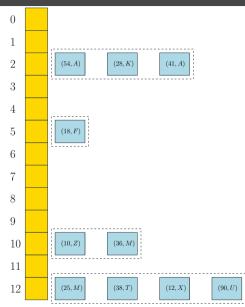

What is a collision?

We say that two records (k_i, v_i) and (k_j, v_j) have **collided** if $h(k_i) = h(k_j)$. This means both of them got mapped to the same array index.

What to do if multiple records map to the same index?

- Choice 1: Separate chaining
- Choice 2: Open addressing

Separate chaining: use a container (linked-list/ArrayList) at every index

Load-factor of hash-tables

$$\lambda = \frac{\text{the number of records present in the map (n)}}{\text{size of the array (N)}}$$

 $\lambda < 1$ is always desired. This implies no container is probably overcrowded, resulting in fast operation speeds. In Java's implementation of hash-tables, by default, load-factors are never allowed to exceed 0.75. If the load-factor exceeds 0.75, the size of the array is increased and all the records present in the map are re-inserted (every one of them). We are allowed to choose a different value for the load-factor.

 \blacksquare In the beginning, when the table is empty, the number of buckets is set to 16 in Java's implementation of hash-tables.

put(k, v)

$\mathtt{put}(k,v)$: inserts the record (k,v) into the map

- 1 i = h(k);
- 2 Let L be the container present at index i;
- 3 Check L to see if a record is already present in L having key k;
- Q If such a record is present in L, the new record (k, v) cannot be inserted;
- **5** Otherwise, insert the record into *L*;
- **6** Compute the current load factor λ ;
- $\mathbf{7}$ If λ exceeds 0.75, execute **rehash()**;

Takes $O(n^2)$ time in the worst-case (when rehashing is needed). If rehashing is not required, it takes O(n) time in the worst-case and O(1) time on average.

 \blacksquare After rehashing, $\lambda \leq 0.75$

rehash()

rehash(): rehashes the map (an internal method)

- 1 Let N be the size of the current array A;
- \bigcirc Create a new array of empty containers A' whose size is 2N;
- 3 Insert every record currently present in the map into the appropriate container in A' using the new compression function $h_2(x) = x \bmod 2N$ but using the old hashcode h_1 (since the type of keys did not change). This step requires n put(k,v) operations.

Rehashing runs in $O(n^2)$ time in the worst case where n is the number of records currently present in the map

Rehashing illustration

```
Bucket 0: [96. Jim] -> [112. Peter]
Bucket 1:
Bucket 2:
Bucket 3: [99. Jack]
Bucket 4: [36. Rose]
Bucket 5:
Bucket 6: [22. Charles]
Bucket 7: [23. Alice]
Bucket 8: [40, Bob]
Bucket 9: [41, Matthew]
Bucket 10: [10. Tom]
Bucket 11: [11. Dorothy]
Bucket 12: [92. Eric]
Bucket 13:
Bucket 14: [62, Donald]
Bucket 15:
```

Load-factor
$$(\lambda) = \frac{n}{N} = \frac{12}{16} = 0.75$$

Bucket 0: [96. lim] Bucket 1: Bucket 2: Bucket 3: [99, Jack] Bucket 4: [36, Rose] Bucket 5: Bucket 6: Bucket 7: Bucket 8: [40, Bob] Bucket 9: [41. Matthew] Bucket 10: [10, Tom] Bucket 11: [11. Dorothy] Bucket 12 - 15: Bucket 16: [112. Peter] Bucket 17 - 21: Bucket 22: [22. Charles] Bucket 23: [23. Alice] Bucket 24 - 27: Bucket 28: [92, Eric] Bucket 29: Bucket 30: [62. Donald] Bucket 31: [31, Tobv]

After inserting [31, Toby], $\lambda = \frac{13}{16} = 0.8125 > 0.75$; rehashing is required; new $\lambda = \frac{n}{N} = \frac{13}{22} \approx 0.40625 \leq 0.75$

get(k)

get(k): returns the value part of the record whose key is k

- 1 i = h(k);
- 2 Let L be the container present at index i;
- 3 Check L to see if a record is already present in L having key k;
- \bigcirc If such a record is present in L, return its value part;
- Otherwise, return null;

Takes O(n) time in the worst-case (when most records map to the same bucket) but in practice takes O(1) time on average

remove(k)

remove(k): removes the record having key k, if present

- 1 i = h(k);
- 2 Let L be the container present at index i;
- 3 Check L to see if a record is present in L having key k;
- (A) If such a record is present in L, remove and return the value part of the record (k,v);
- Otherwise, return null;

Takes O(n) time in the worst-case (when most records map to the same bucket) but in practice takes O(1) time on average

Code

See the class HashMapSeparateChaining

In our implementation, the containers are **singly linked-lists**

Worst-case scenario of separate chaining

- In the worst case, most of the records can map to the same index!
- Thus, insertion, deletion, and searching take O(n) time in the worst-case if lists are used and $O(\log n)$ time if RB-trees are used
- In such cases, we do not get any advantage out of hashing
- However, if we are using good hash function, these extreme situations will almost never happen and we get super-speedy performance in the real-world

Open addressing

- Use an array of size N
- At every index, we can store at most one record
- If the desired index is occupied, we find the next available spot using some technique
- Let us look at such a popular technique known as LINEAR PROBING
- If the spot is already occupied by some other record (collision), we consider the next available spot in the array by wrapping around

Example

0	1	2	3	4	5	6	7	8	9	10

Insert (13, A)

0	1	2	3	4	5	6	7	8	9	10
		(13, A)								

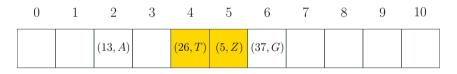

Insert (26,T)

0	1	2	3	4	5	6	7	8	9	10
		(13, A)		(26,T)						

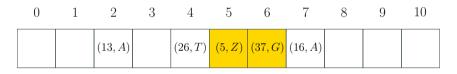

Insert (5, Z)

0	1	2	3	4	5	6	7	8	9	10
		(13, A)		(26,T)	(5, Z)					

Insert (37, G); collision!

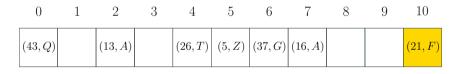

Insert (16, A); collision!

Insert (21, F)

0	1	2	3	4	5	6	7	8	9	10
		(13, A)		(26,T)	(5, Z)	(37, G)	(16, A)			(21, F)

Insert (43, Q); collision!

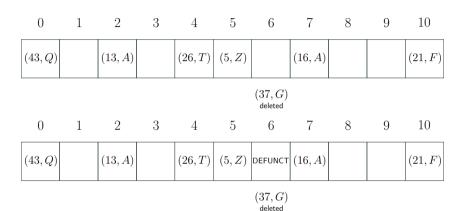

Operations

In the following, **DEFUNCT** is a special record whose key and value are set to null

- 1 Insertion. Use the hash function on the key to obtain the target index; then use linear probing to find the next available (with wrap-around) spot; cells having **DEFUNCT** are considered to be empty
- **Searching.** Use the hash function on the key to obtain the index; then do a wrap-around linear probe to search the record. If an empty spot is encountered, the desired record is not present. However, skip over the cells containing **DEFUNCT**.
- 3 **Deletion.** Use the hash function on the key to obtain the target index; using linear probing located the record if present starting at the target index; then delete the record from the cell and put a special symbol **DEFUNCT** in its place (see the example next to see why)

All these three operations takes O(n) time in the worst-case

Why DEFUNCT is necessary?

Search for (16, A) will fail if we put store null at index 6

Observations

- If we are using open addressing, the number of records that can be present in the array cannot exceed the array size since we are not using chaining
- But it is not the case in separate chaining
- Separate chaining consumes more space to maintain the containers at every index
